JSON Meta Application Protocol
draft-ietf-jmap-core-02

Abstract

This document specifies a protocol for synchronising JSON-based data objects efficiently, with support for push and out-of-band binary data upload/download.

Status of This Memo

This Internet-Draft is submitted in full conformance with the provisions of BCP 78 and BCP 79.

Internet-Drafts are working documents of the Internet Engineering Task Force (IETF). Note that other groups may also distribute working documents as Internet-Drafts. The list of current Internet-Drafts is at https://datatracker.ietf.org/drafts/current/.

Internet-Drafts are draft documents valid for a maximum of six months and may be updated, replaced, or obsoleted by other documents at any time. It is inappropriate to use Internet-Drafts as reference material or to cite them other than as "work in progress."

This Internet-Draft will expire on May 3, 2018.

1. Introduction

JMAP is a generic protocol for synchronising data, such as mail, calendars or contacts, between a client and a server. It is optimised for mobile and web environments, and aims to provide a consistent interface to different data types.

This specification is for the generic mechanism of data synchronisation. Further specifications define the data models for different data types that may be synchronised via JMAP.

JMAP is designed to make efficient use of limited network resources. Multiple API calls may be batched in a single request to the server, reducing round trips and improving battery life on mobile devices. Push connections remove the need for polling, and an efficient delta update mechanism ensures a minimum of data is transferred.

JMAP is designed to be horizontally scalable to a very large number of users. This is facilitated by the separate end points for users after login, the separation of binary and structured data, and a shared data model that does not allow data dependencies between accounts.

1.1. Notational conventions

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in [RFC2119].

The underlying format used for this specification is JSON. Consequently, the terms "object" and "array" as well as the four primitive types (strings, numbers, booleans, and null) are to be interpreted as described in Section 1 of [RFC7159]. Unless otherwise noted, all the property names and values are case sensitive.

Some examples in this document contain "partial" JSON documents used for illustrative purposes. In these examples, three periods "..." are used to indicate a portion of the document that has been removed for compactness.

Types signatures are given for all JSON objects in this document. The following conventions are used:
o "Boolean|String" - The value is either a JSON "Boolean" value, or a JSON "String" value.

o "Foo" - Any name that is not a native JSON type means an object for which the properties (and their types) are defined elsewhere within this document.

o "Foo[]" - An array of objects of type "Foo".

o "String[Foo][]" - A JSON "Object" being used as a map (associative array), where all the values are of type "Foo".

1.2. The Number datatype

The JSON datatypes are limited to those found in JavaScript. A "Number" in JavaScript is represented as a signed double (64-bit floating point). However, except where explicitly specified, all numbers used in this API are unsigned integers <= 2^53 (the maximum integer that may be reliably stored in a double). This implicitly limits the maximum length of message lists in queries and the like.

1.3. The Date datatypes

Where a JMAP API specifies "Date" as a type, it means a string in [RFC3339] _date-time_ format, with the _time-offset_ component always "Z" (i.e. the date-time MUST be in UTC time) and _time-secfrac_ always omitted. The "T" and "Z" MUST always be upper-case. For example, "2014-10-30T14:12:00Z".

1.4. JSON as the data encoding format

JSON is a text-based data interchange format as specified in [RFC7159]. The I-JSON format defined in [RFC7493] is a strict subset of this, adding restrictions to avoid potentially confusing scenarios (for example, it mandates that an object MUST NOT have two properties with the same key).

All data sent from the client to the server or from the server to the client (except binary file upload/download) MUST be valid I-JSON according to the RFC, and is therefore case-sensitive and encoded in UTF-8 ([RFC3629]).

1.5. Terminology
1.5.1. User

A user represents a set of permissions relating to what data can be seen.

1.5.2. Accounts

An account is a collection of data.

All data, other than the Account objects themselves, belong to a single account. A single account may contain an arbitrary set of data, for example a collection of mail, contacts and calendars. Most operations in JMAP are isolated to a single account; there are a few explicit operations to copy data between them. Certain properties are guaranteed for data within the same account, for example uniqueness of ids within a type in that account.

An account is not the same as a user, although it is common for the primary account to directly belong to the user. For example, you may have an account that contains data for a group or business, to which multiple users have access. Users may also have access to accounts belonging to another user if that user is sharing some of their data.

1.5.3. Data types and records

JMAP provides a uniform interface for creating, retrieving, updating and deleting various types of objects. A *data type* is a collection of named, typed properties, just like the schema for a database table. Each instance of a data type is called a *record*.

1.6. Ids

All object ids are assigned by the server, and are immutable. They MUST be unique among all objects of the *same type* within the *same account*. Ids may clash across accounts, or for two objects of different types within the same account.

Ids are always "String"s. An id MUST be a valid UTF-8 string of at least 1 character in length and maximum 256 bytes in size, but MUST NOT start with the "#" character, as this is reserved for doing back references during object creation (see the _setFoos_ description).

1.7. The JMAP API model

JMAP uses HTTP [RFC7230] to expose API, Push, Upload and Download resources. Implementations MUST support HTTP/1.1, and MAY support later versions. Support for common HTTP mechanisms such as redirection and caching are assumed.
All HTTP requests MUST be authenticated. Servers MUST conform with the [RFC7235] HTTP Authentication framework to reject requests that fail authentication and inform the client of available authentication schemes.

Clients SHOULD understand and be able to handle standard HTTP status codes appropriately.

An authenticated client can fetch the JMAP session object with details about the data and capabilities the server can provide as shown in section 2. The client may then exchange data with the server using four different mechanisms:

1. The client may make an API request to the server to get or set structured data. This request consists of an ordered series of method calls. These are processed by the server, which then returns an ordered series of responses. This is described in section 3.

2. The client may download binary files from the server. This is detailed in section 4.

3. The client may upload binary files to the server. This is specified in section 5.

4. The client may connect to a push channel on the server, to be notified when data has changed. This is explained in section 6.

2. The JMAP session resource

To communicate with a JMAP server you need two things to start:

1. The URL for the JMAP session resource. This may be requested directly from the user, or discovered automatically based on a username domain (see Service Autodiscovery section below).

2. Credentials to authenticate with. How to obtain credentials is out of scope for this specification.

An authenticated GET request to the JMAP session resource MUST return the details about the data and capabilities the server can provide to the client given those credentials.

The response to a successful request is a JSON object with the following properties:

- *username*: "String" The username associated with the given credentials.
*accounts*: "String[Account]" A map of *account id* to Account object for each account the user has access to. A single set of credentials may provide access to multiple accounts, for example if another user is sharing their mail with the logged in user, or if there is an account that contains data for a group or business. All data belongs to a single account. With the exception of a few explicit operations to copy data between accounts, all JMAP methods take an _accountId_ argument that specifies on which account the operations are to take place. This argument is always optional; if not specified, the primary account is used. All ids (other than Account ids of course) are only unique within their account. In the event of a severe internal error, a server may have to reallocate ids or do something else that violates standard JMAP data constraints. In this situation, the data on the server is no longer compatible with cached data the client may have from before. The server MUST treat this as though the account has been deleted and then recreated with a new account id. Clients will then be forced to throw away any data with the old account id and refetch all data from scratch. An *Account* object has the following properties:

* *name*: "String" A user-friendly string to show when presenting content from this account, e.g. the email address representing the owner of the account.

* *isPrimary*: "Boolean" This MUST be true for *at most* one of the accounts returned. This is to be considered the user’s main or default account by the client. If no account being returned belongs to the user, or in any other way there is no appropriate way to determine a default account, then this MAY be "false" for all accounts.

* *isReadOnly*: "Boolean" This is "true" if the entire account is read-only.

* *hasDataFor*: "String[]" A list of the data profiles available in this account. Each future JMAP data types specification will define a profile name to encompass that set of types.

* *capabilities*: "String[Object]" An object specifying the capabilities of this server. The keys are URIs, which specify the specifications supported by the server. The value for each of these keys is an object that MAY include further information about the server’s capabilities in relation to that spec. The client MUST ignore any properties it does not understand. The capabilities object MUST include a property called "'(TODO: URI for this spec)'". The value of this property is an object which SHOULD contain the following information on server capabilities:
* *maxSizeUpload*: "Number" The maximum file size, in bytes, that the server will accept for a single file upload (for any purpose).

* *maxConcurrentUpload*: "Number" The maximum number of concurrent requests the server will accept to the upload endpoint.

* *maxSizeRequest*: "Number" The maximum size, in bytes, that the server will accept for a single request to the API endpoint.

* *maxConcurrentRequests*: "Number" The maximum number of concurrent requests the server will accept to the API endpoint.

* *maxCallsInRequest*: "Number" The maximum number of method calls the server will accept in a single request to the API endpoint.

* *maxObjectsInGet*: "Number" The maximum number of objects that the client may request in a single "getFoos" type method call.

* *maxObjectsInSet*: "Number" The maximum number of objects the client may send to create, update or destroy in a single "setFoos" type method call.

Future specifications will define their own properties on the capabilities object.

  o *apiUrl*: "String" The URL to use for JMAP API requests.

  o *downloadUrl*: "String" The URL endpoint to use when downloading files (see the Download section of this spec), in [RFC6570] URI Template (level 1) format. The URL MUST contain variables called "blobId", MAY contain a variables called "accountId" and SHOULD contain a variable called "name".

  o *uploadUrl*: "String" The URL endpoint to use when uploading files (see the Upload section of this spec).

  o *eventSourceUrl*: "String" The URL to connect to for push events (see the Push section of this spec).

2.1. Service Autodiscovery

There are two standardised autodiscovery methods in use for internet protocols:

  o *DNS srv* ([RFC6186] and [RFC6764])
A JMAP-supporting host for the domain "example.com" SHOULD publish a SRV record ".jmaps._tcp.example.com" which gives a _hostname_ and _port_ (usually port "443"). The JMAP Session resource is then "https://${hostname}:${port}/.well-known/jmap" (following any redirects).

If the client has a username in the form of an email address, it MAY use the domain portion of this to attempt autodiscovery of the JMAP server.

To support clients that are unable to do SRV lookups, the server SHOULD make the _hostname_ the same domain as the username if possible.

3. Structured data exchange

The client may make an API request to the server to get or set structured data. This request consists of an ordered series of method calls. These are processed by the server, which then returns an ordered series of responses.

3.1. Making an API request

To make an API request, the client makes an authenticated POST request to the API resource, the location of which may be found on the JMAP session object.

The request MUST have a content type of "application/json" and be encoded in UTF-8.

If successful, the response will be of type "application/json" and consist of the response to the API calls, as described below.

3.2. The structure of an API request

The client initiates an API request by sending the server a JSON array. Each element in this array is another array representing a method invocation on the server. The server will process the method calls and return a response consisting of an array in the same format. Each method call always contains three elements:

1. The *name* of the method to call, or the name of the response from the server. This is a "String".

2. An "Object" containing _named_ *arguments* for that method or response.
3. A *client id*: an arbitrary "String" to be echoed back with the responses emitted by that method call (a method may return 1 or more responses, as it may make implicit calls to other methods; all responses initiated by this method call get the same client id in the response).

Example query:

```javascript
["method1", {"arg1": "arg1data", "arg2": "arg2data"}, "#1"],
["method2", {"arg1": "arg1data"}, "#2"],
["method3", {}, "#3"]
```

The method calls MUST be processed sequentially, in order. Each API request (which, as shown, may contain multiple method calls) receives a JSON response in exactly the same format. The output of the methods MUST be added to the array in the same order as the methods are processed.

Example response:

```javascript
["responseFromMethod1", {"arg1": 3, "arg2": "foo"}, "#1"],
"responseFromMethod2", {"isBlah": true}, "#2"],
["anotherResponseFromMethod2", {
  "data": 10,
  "yetmoredata": "Hello"
}, "#2"],
["aResponseFromMethod3", {}, "#3"]
```

3.3. Omitting arguments

An argument to a method may be specified to have a default value. If omitted by the client, the server MUST treat the method call the same as if the default value had been specified. Similarly, the server MAY omit any argument in a response which has the default value.

Unless otherwise specified in a method description, "null" is the default value for any argument in a request or response where this is allowed by the type signature. Other arguments may only be omitted if an explicit default value is defined in the method description.
3.4. Errors

If the data sent as an API request is not valid JSON or does not match the structure above, a "400 Bad Request" error will be returned at the HTTP level.

Possible errors for each method are specified in the method descriptions. If a method encounters an error, the appropriate "error" response MUST be inserted at the current point in the output array and, unless otherwise specified, further processing MUST NOT happen within that method call.

Any further method calls in the request MUST then be processed as normal.

An "error" response looks like this:

```json
["error", {
  type: "unknownMethod"
}, "client-id"]
```

The response name is "error", and it has a type property as specified in the method description. Other properties may be present with further information; these are detailed in the method descriptions where appropriate.

Any method MAY return an error of type "serverError" if an unexpected or unknown error occurs during the processing of that call. The state of the server after such an error is undefined.

If an unknown method is called, an "unknownMethod" error (this is the type shown in the example above) MUST be inserted and then the next method call MUST be processed as normal.

If an unknown argument or invalid arguments (wrong type, missing and not optional, or in violation of other specified constraints) are supplied to a method, an "invalidArguments" error MUST be inserted and then the next method call MUST be processed as normal.

3.5. References to previous method results

To allow clients to make more efficient use of the network and avoid round trips, an argument to one method can be taken from the result of a previous method call.

To do this, the client prefixes the argument name with "#". The value is a _ResultReference_ object as described below. When processing a method call, the server MUST first check the arguments
object for any names beginning with "#". If found, the back reference should be resolved and the value used as the "real" argument. The method is then processed as normal. If any back reference fails to resolve, the whole method MUST be rejected with a "resultReference" error.

A *ResultReference* object has the following properties:

- **resultOf**: "String" The client id of the method call to get the result from (the string given as the third item in the array for a method call).

- **path**: "String" A pointer into the arguments. This is an RFC6901 JSON Pointer, except it also allows the use of "*" to map through an array (see description below).

To resolve:

1. Find the first response with a client id identical to the _resultOf_ property of the _ResultReference_ in the array of outputs from previously processed method calls in the same request. If none, evaluation fails.

2. If the response name is "error", evaluation fails.

3. Apply the _path_ to the arguments object of the response (the second item in the response array) following the [RFC6901] JSON pointer algorithm, except with the following addition in Section 4 (Evaluation):

   - If the currently referenced value is a JSON array, the reference token may be exactly the single character "*", making the new referenced value the result of applying the rest of the JSON pointer tokens to every item in the array and returning the results in the same order in a new array. If the result of applying the rest of the pointer tokens to a value was itself an array, its items should be included individually in the output rather than including the array itself (i.e. the result is flattened from an array of arrays to a single array).

   1. If the type of the result is X, and the expected type of the argument is an array of type X, wrap the result in an array with a single item.

As a simple example, suppose we have the following API request:
Internet-Draft  JMAP                      October 2017

[[ "getFooUpdates", {
   "sinceState": "abcdef"
}, "t0" ],
 [ "getFoos", {
    "#ids": {
       "resultOf": "t0",
       "path": "/changed"
    }
 }, "t1" ]]

After executing the first method call the response array is:

[[ "fooUpdates", {
   "accountId": "1",
   "oldState": "abcdef",
   "newState": "123456",
   "hasMoreUpdates": false,
   "changed": [ "f1", "f4" ],
   "removed": []
 }, "t0" ]]

So to execute the getFoos call, we look through the arguments and find there is one with a "#" prefix. To resolve this, we apply the algorithm above:

1. Find the first response with client id "t0". The "fooUpdates" response fulfills this criterion.

2. Check the response name is not "error". It’s "fooUpdates", so this is fine.

3. Apply the _path_ as a JSON pointer to the arguments object. This simply selects the "changed" property, so the result of evaluating is: "[ "f1", "f4" ]"

The JMAP server now continues to process the getFoos call as though the arguments were:

    {
      "ids": [ "msg1", "msg4" ]
    }

Now a more complicated example using the JMAP Mail data model: fetch the "from"/"date"/"subject" for every message in the first 10 threads in the Inbox (sorted newest first):
After executing the first 3 method calls the response array might be:
[[ "messageList", {
   "accountId": "1",
   "filter": { inMailbox: "id_of_inbox" },
   "sort": [ "date desc" ],
   "collapseThreads": true,
   "state": "abcdefg",
   "canCalculateUpdates": true,
   "position": 0,
   "total": 101,
   "ids": [ "msg1023", "msg223", "msg110", "msg93", "msg91", "msg38", "msg36", "msg33", "msg11", "msg1" ]
} ], "t0" ],
[ "messages", {
   "accountId": "1",
   "state": "123456",
   "list": [{
      "id": "msg1023",
      "threadId": "trd194",
   }, {
      "id": "msg223",
      "threadId": "trd114"
   }, ...
   },
   "notFound": null
} ], "t1" ],
[ "threads", {
   "accountId": "1",
   "state": "123456",
   "list": [{
      "id": "trd194",
      "messageIds": [ "msg1020", "msg1021", "msg1023" ]
   }, {
      "id": "trd114",
      "messageIds": [ "msg201", "msg223" ]
   }, ...
   },
   "notFound": null
} ], "t2" ]

So to execute the final getMessages call, we look through the arguments and find there is one with a "#" prefix. To resolve this, we apply the algorithm:

1. Find the first response with client id "t2". The "threads" response fulfills this criterion.
2. Check the response name is not "error". It’s threads", so this
is fine.

3. Apply the _path_ as a JSON pointer to the arguments object.
   Token-by-token: a) "list": get the array of thread objects b)
   "**": for each of the items in the array: i) "messsageIds": get
   the array of message ids ii) Concatenate these into a single
   array of all the ids in the result.

   The JMAP server now continues to process the getMessages call as
   though the arguments were:

   {
     "ids": [ "msg1020", "msg1021", "msg1023", "msg201", "msg223", etc... ],
     "properties": [ "from", "date", "subject" ]
   }

3.6. Vendor-specific extensions

   Individual services will have custom features they wish to expose
   over JMAP. This may take the form of extra datatypes and/or methods
   not in the spec, or extra arguments to JMAP methods, or extra
   properties on existing data types (which may also appear in arguments
   to methods that take property names). To ensure compatibility with
   clients that don’t know about a specific custom extension, and for
   compatibility with future versions of JMAP, the server MUST ONLY
   expose these extensions if the client explicitly opts in. Without
   opt-in, the server MUST follow the spec and reject anything that does
   not conform to it as specified.

3.7. Security

   As always, the server must be strict about data received from the
   client. Arguments need to be checked for validity; a malicious user
   could attempt to find an exploit through the API. In case of invalid
   arguments (unknown/insufficient/wrong type for data etc.) the method
   MUST return an "invalidArguments" error and terminate.

3.8. Concurrency

   Each individual method call within a request MUST be serializable;
   concurrent execution of methods MUST produce the same effect as
   running them one at a time in some order.

   This means that the observable ordering may interleave method calls
   from different concurrent API requests, such that the data on the
   server may change between two method calls within a single API
   request.
4. Standard methods and naming convention

JMAP provides a uniform interface for creating, retrieving, updating and deleting objects of a particular type. For a "Foo" data type, records of that type would be fetched via a "getFoos" call and modified via a "setFoos" call. Delta updates may be fetched via a "getFooUpdates" call. These methods all follow a standard format as described below.

Methods with a name starting with "get" MUST NOT alter state on the server.

4.1. getFoos

Objects of type "Foo" are fetched via a call to _getFoos_.

It takes the following arguments:

- *accountId*: "String|null" The id of the Account to use. If "null", the primary account is used.
- *ids*: "String[]|null" The ids of the Foo objects to return. If "null" then *all* records of the data type are returned, if this is supported for that data type.
- *properties*: "String[]|null" If supplied, only the properties listed in the array are returned for each Foo object. If "null", all properties of the object are returned. The id of the object is *always* returned, even if not explicitly requested.

The response to "getFoos" is called "foos". It has the following arguments:

- *accountId*: "String" The id of the account used for the call.
- *state*: "String" A string representing the state on the server for *all* the data of this type in the account (not just the objects returned in this call). If the data changes, this string MUST change. If the Foo data is unchanged, servers SHOULD return the same state string on subsequent requests for this data type. When a client receives a response with a different state string to a previous call, it MUST either throw away all currently cached objects for the type, or call _getFooUpdates_ to get the exact changes.
- *list*: "Foo[]" An array of the Foo objects requested. This is the *empty array* if no objects were found, or if the _ids_ argument passed in was also the empty array. The results MAY be
in a different order to the _ids_ in the request arguments. If an identical id is included more than once in the request, the server MUST only include it once in the _list_ or _notFound_ response.

- *notFound*: "String[]"|null" This array contains the ids passed to the method for records that do not exist. This property is "null" if all requested ids were found, or if the _ids_ argument passed in was either "null" or the empty array.

The following error may be returned instead of the "foos" response:

- "accountNotFound": An _accountId_ was explicitly included with the request, but it does not correspond to a valid account.
- "accountNotSupportedByMethod": The _accountId_ given corresponds to a valid account, but the account does not support this data type.
- "requestTooLarge": The number of _ids_ requested by the client exceeds the maximum number the server is willing to process in a single method call.
- "invalidArguments": One of the arguments is of the wrong type, or otherwise invalid. A "description" property MAY be present on the response object to help debug with an explanation of what the problem was.

### 4.2. getFooUpdates

When the state of the set of Foo records changes on the server (whether due to creation, updates or deletion), the _state_ property of the _foos_ response will change. The _getFooUpdates_ call allows a client to efficiently update the state of its Foo cache to match the new state on the server. It takes the following arguments:

- *accountId*: "String"|null" The id of the Account to use. If "null", the primary account is used.
- *sinceState*: "String" The current state of the client. This is the string that was returned as the _state_ argument in the _foos_ response. The server will return the changes made since this state.
- *maxChanges*: "Number"|null" The maximum number of ids to return in the response. The server MAY choose to return fewer than this value, but MUST NOT return more. If not given by the client, the server may choose how many to return. If supplied by the client, the value MUST be a positive integer greater than 0. If a value
outside of this range is given, the server MUST reject the call with an "invalidArguments" error.

The response to _getFooUpdates_ is called _fooUpdates_. It has the following arguments:

- **accountId**: "String" The id of the account used for the call.
- **oldState**: "String" This is the _sinceState_ argument echoed back; the state from which the server is returning changes.
- **newState**: "String" This is the state the client will be in after applying the set of changes to the old state.
- **hasMoreUpdates**: "Boolean" If "true", the client may call _getFooUpdates_ again with the _newState_ returned to get further updates. If "false", _newState_ is the current server state.
- **changed**: "String[]|null" An array of ids for records which have been created or changed but not destroyed since the oldState, or "null" if none.
- **removed**: "String[]|null" An array of ids for records which have been destroyed since the old state, or "null" if none.

If a _maxChanges_ is supplied, or set automatically by the server, the server MUST ensure the number of ids returned across _changed_ and _removed_ does not exceed this limit. If there are more changes than this between the client’s state and the current server state, the update returned SHOULD generate an update to take the client to an intermediate state, from which the client can continue to call _getMessageUpdates_ until it is fully up to date. If it is unable to calculate an intermediate state, it MUST return a "cannotCalculateChanges" error response instead.

If a Foo record has been modified AND deleted since the oldState, the server SHOULD just return the id in the _removed_ response, but MAY return it in the changed response as well. If a Foo record has been created AND deleted since the oldState, the server SHOULD remove the id from the response entirely, but MAY include it in the _removed_ response.

The following errors may be returned instead of the _fooUpdates_ response:

- "accountNotFound": An _accountId_ was explicitly included with the request, but it does not correspond to a valid account.
"accountNotSupportedByMethod": The _accountId_ given corresponds to a valid account, but the account does not support this data type.

"invalidArguments": The request does not include one of the required arguments, or one of the arguments is of the wrong type, or otherwise invalid. A _description_ property MAY be present on the response object to help debug with an explanation of what the problem was.

"cannotCalculateChanges": The server cannot calculate the changes from the state string given by the client. Usually due to the client’s state being too old, or the server being unable to produce an update to an intermediate state when there are too many updates. The client MUST invalidate its Foo cache.

Maintaining state to allow calculation of _getFooUpdates_ can be expensive for the server, but always returning _cannotCalculateChanges_ severely increases network traffic and resource usage for the client. To allow efficient sync, servers SHOULD be able to calculate changes from any state string that was given to a client within the last 30 days (but of course may support calculating updates from states older than this).

4.3. setFoos

Modifying the state of Foo objects on the server is done via the _setFoos_ method. This encompasses creating, updating and destroying Foo records. This allows the server to sort out ordering and dependencies that may exist if doing multiple operations at once (for example to ensure there is always a minimum number of a certain record type).

The _setFoos_ method takes the following arguments:

- *accountId*: "String|null" The id of the Account to use. If "null", the primary account is used.

- *ifInState*: "String|null" This is a state string as returned by the _getFoos_ method. If supplied, the string must match the current state, otherwise the method will be aborted and a "stateMismatch" error returned. If "null", any changes will be applied to the current state.

- *create*: "String[Foo]|null" A map of _creation id_ (an arbitrary string set by the client) to Foo objects, or "null" if no objects are to be created. The Foo object type definition MAY define default values for properties. Any such property MAY be omitted by the client. The client MUST omit any properties that may only
be set by the server (for example, the _id_ property on most
object types).

- **update**: "String[PatchObject]|null" A map of id to a Patch object
to apply to the current Foo object with that id, or "null" if no
objects are to be updated. A _PatchObject_ is of type
"String[*]", and represents an unordered set of patches. The keys
are a path in [RFC6901] JSON pointer format, with an implicit
leading "/" (i.e. prefix each key with "/" before applying the
JSON pointer evaluation algorithm). All paths MUST also conform
to the following restrictions; if there is any violation, the
update MUST be rejected with an "invalidPatch" error:

  * The pointer MUST NOT reference inside an array (i.e. you MUST
    NOT insert/delete from an array; the array MUST be replaced in
    its entirety instead).

  * All parts prior to the last (i.e. the value after the final
    slash) MUST already exist on the object being patched.

  * There MUST NOT be two patches in the PatchObject where the
    pointer of one is the prefix of the pointer of the other, e.g.
    "alerts/1/offset" and "alerts".

The value associated with each pointer determines how to apply
that patch:

  * If "null", set to the default value if specified for this
    property, otherwise remove the property from the patched
    object. If the key is not present in the parent, this a no-op.

  * Anything else: The value to set for this property (this may be
    a replacement or addition to the object being patched).

Any server-set properties MAY be included in the patch if their
value is identical to the current server value (before applying
the patches to the object). Otherwise, the update MUST be
rejected with an _invalidProperties_ SetError. This patch
definition is designed such that an entire Foo object is also a
valid PatchObject. The client MAY choose to optimise network
usage by just sending the diff, or MAY just send the whole object;
the server processes it the same either way.

- **destroy**: "String[]|null" A list of ids for Foo objects to
  permanently delete, or "null" if no objects are to be destroyed.

Each creation, modification or destruction of an object is considered
an atomic unit. It is permissible for the server to commit changes
to some objects but not others, however it is not permissible to only commit part of an update to a single record (e.g. update a _name_ property but not a _count_ property, if both are supplied in the update object).

The final state MUST be valid after the setFoos is finished, however the server may have to transition through invalid intermediate states (not exposed to the client) while processing the individual create/update/destroy requests. For example, suppose there is a "name" property that must be unique. A single method call could rename an object A => B, and simultaneously rename another object B => A. The final state is valid, so this is allowed, however if processed sequentially there will be an internal state where temporarily both objects have the same name.

If a create, update or destroy is rejected, the appropriate error MUST be added to the notCreated/notUpdated/notDestroyed property of the response and the server MUST continue to the next create/update/destroy. It does not terminate the method.

If an id given cannot be found, the update or destroy MUST be rejected with a "notFound" set error.

Some record objects may hold references to others (foreign keys). When records are created or modified, they may reference other records being created _in the same API request_ by using the creation id prefixed with a "#". The order of the method calls in the request by the client MUST be such that the record being referenced is created in the same or an earlier call. The server thus never has to look ahead. Instead, while processing a request (a series of method calls), the server MUST keep a simple map for the duration of the request of creation id to record id for each newly created record, so it can substitute in the correct value if necessary in later method calls.

Creation ids are scoped by type; a separate "creation id -> id" map MUST be kept for each type for the duration of the request. Foreign key references are always for a particular record type, so use of the same creation key in two different types cannot cause any ambiguity. Creation ids sent by the client SHOULD be unique within the single API request for a particular data type. If a creation id is reused for the same type, the server MUST map the creation id to the most recently created item with that id.

The response to _setFoos_ is called _foosSet_. It has the following arguments:

- "accountId": "String" The id of the account used for the call.
- *oldState*: "String|null" The state string that would have been returned by _getFoos_ before making the requested changes, or "null" if the server doesn’t know what the previous state string was.

- *newState*: "String" The state string that will now be returned by _getFoos_.

- *created*: "String[ Foo]|null" A map of the creation id to an object containing any properties of the created Foo object that were not sent by the client. This includes all server-set properties (such as the _id_ in most object types) and any properties that were omitted by the client and so set to a default by the server. This argument is "null" if no Foo objects were successfully created.

- *updated*: "String[ Foo]|null" The _keys_ in this map are the ids of all Foos that were successfully updated, or "null" if none successful. The _value_ for each id is a Foo object containing any property that changed in a way _not_ explicitly requested by the _PatchObject_ sent to the server, or "null" if none. This lets the client know of any changes to server-set or computed properties.

- *destroyed*: "String[]|null" A list of Foo ids for records that were successfully destroyed, or "null" if none successful.

- *notCreated*: "String[ SetError]|null" A map of creation id to a SetError object for each record that failed to be created, or "null" if all successful.

- *notUpdated*: "String[ SetError]|null" A map of Foo id to a SetError object for each record that failed to be updated, or "null" if all successful.

- *notDestroyed*: "String[ SetError]|null" A map of Foo id to a SetError object for each record that failed to be destroyed, or "null" if all successful.

A *SetError* object has the following properties:

- *type*: "String" The type of error.

- *description*: "String|null" A description of the error to display to the user.

The following SetError types are defined and may be returned for set operations on any record type:
The following errors may be returned instead of the "foosSet" response:

"accountNotFound": An _accountId_ was explicitly included with the request, but it does not correspond to a valid account.

"accountNotSupportedByMethod": The _accountId_ given corresponds to a valid account, but the account does not support this data type.

"accountReadOnly": The account has isReadOnly == true.

"requestTooLarge": The total number of objects to create, update or destroy exceeds the maximum number the server is willing to process in a single method call.
"invalidArguments": One of the arguments is of the wrong type, or otherwise invalid. A "description" property MAY be present on the response object to help debug with an explanation of what the problem was.

"stateMismatch": An "ifInState" argument was supplied and it does not match the current state.

4.3.1. Example

Suppose we have a type `_Todo_` with the following properties:

- *id*: "String" (immutable; server-set) The id of the object.
- *title*: "String" The "From" _name_ the client SHOULD use when creating a new message from this identity.
- *keywords*: "String[Boolean]" (mutable; default: "{}") A set of keywords that apply to the message. The set is represented as an object, with the keys being the _keywords_. The value for each key in the object MUST be "true".
- *neuralNetworkTimeEstimation*: "Number" (server-set) The title and keywords are fed into the server’s state-of-the-art neural network to get an estimation of how long this todo will take, in seconds.

Now we fetched a Todo of id "a" (let’s presume we already knew a Todo with this id existed):

```javascript
["getTodos", {
  "ids": ["a"]
}, "0"]
```

and got back
["todos", {
  "accountId": "x",
  "state": "10324",
  "list": [
    {
      "id": "a",
      "title": "Practice Piano",
      "keywords": {
        "beethoven": true,
        "mozart": true,
        "liszt": true,
        "rachmaninov": true,
      },
      "neuralNetworkTimeEstimation": 3600
    }
  ],
  "0"
}]

Now the user adds a keyword "chopin" and removes the keyword "mozart". The client may send the whole object to the server, as this is a valid PatchObject:

["setTodos", {
  "ifInState": "10324",
  "update": {
    "a": {
      "id": "a",
      "title": "Practice Piano",
      "keywords": {
        "beethoven": true,
        "chopin": true,
        "liszt": true,
        "rachmaninov": true,
      },
      "neuralNetworkTimeEstimation": 360
    }
  },
  "0"
}]

or it may send a minimal patch:

["setTodos", {
  "ifInState": "10324",
  "update": {
    "a": {
      "keywords/chopin": true,
      "keywords/mozart": null
    }
  },
  "0"
}]
The effect is exactly the same on the server in either case, and presuming the server is still in state "10324" it will probably return success:

```json
["todosSet", {
  "accountId": "x",
  "oldState": "10324",
  "newState": "10329",
  "updated": {
    "a": {
      "neuralNetworkTimeEstimation": 5400
    }
  }, "0"]
```

The server changed the "neuralNetworkTimeEstimation" property on the object as part of this change; as this changed in a way _not_ explicitly requested by the PatchObject sent to the server, it is returned with the "updated" confirmation.

4.4.  getFooList

For data sets where the total amount of data is expected to be very small, clients can just fetch the complete set of data and then do any sorting/filtering locally. However, for large data sets (e.g. multi-gigabyte mailboxes), the client needs to be able to perform a query on the server for the data type.

A query on the set of Foos in an account is made by calling _getFooList_. This takes a number of arguments to determine which records to include, how they should be sorted, and which part of the result should be returned (the full list may be _very_ long). The result is returned as a list of Foo ids.

A call to _getFooList_ takes the following arguments:

- *accountId*: "String|null" The id of the Account to use. If "null", the primary account is used.

- *filter*: "FilterCondition|null" Determines the set of Foos returned in the results. This is an "object", whose allowed properties and semantics depend on the data type. If "null", all objects in the account of this type are included in the results.

- *sort*: "String[]|null" Lists the names of properties to compare between two Foo records to determine which comes first in the sort. If two Foo records have an identical value for the first property, the next property will be considered and so on. If all
properties are the same (this includes the case where an empty array or "null" is given as the _sort_ argument), the sort order is server-dependent, but MUST be stable between calls to "getFooList". Following each property name there MUST be a space and then either the string "asc" or "desc" to specify ascending or descending sort for that property. e.g. "[ "date desc", "name asc" ]" The method of comparison depends on the type of the property:

* "String": Comparison function is server-dependent. It SHOULD be case-insensitive and SHOULD take into account locale-specific conventions if known for the user. However, the server MAY choose to just sort based on unicode code point, after best-effort translation to lower-case.

* "Date": If sorting in ascending order, the earlier date MUST come first.

* "Boolean": If sorting in ascending order, a "false" value MUST come before a "true" value.

* "position": "Number" (default: "0") The 0-based index of the first id in the full list of results to return. If a negative value is given, the call MUST be rejected with an "invalidArguments" error. If the index is greater than or equal to the total number of objects in the results list then there are no results to return, but this is not an error.

* "anchor": "String|null" A Foo id. If supplied the _position_ argument is ignored. The index of this id in the results will be used in combination with the "anchorOffset" argument to determine the index of the first result to return (see below for more details).

* "anchorOffset": "Number|null" The index of the anchor object relative to the index of the first result to return. This MAY be negative. For example, "-1" means the first message after the anchor message should be the first result in the results returned (see below for more details).

* "limit": "Number|null" The maximum number of results to return. If "null", no limit presumed. The server MAY choose to enforce a maximum "limit" argument. In this case, if a greater value is given (or if it is "null"), the limit should be clamped to the maximum; since the total number of results in the list is returned, the client can determine if it has received all the results. If a negative value is given, the call MUST be rejected with an "invalidArguments" error.
If an *anchor* argument is given, then after filtering and sorting
the anchor is searched for in the results list. If found, the
*anchor offset* is then subtracted from this index. If the resulting
index is now negative, it is clamped to 0. This index is now used
exactly as though it were supplied as the "position" argument. If
the anchor is not found, the call is rejected with an
"anchorNotFound" error.

If an _anchor_ is specified, any position argument supplied by the
client MUST be ignored. If _anchorOffset_ is "null", it defaults to
"0". If no _anchor_ is supplied, any anchor offset argument MUST be
ignored.

A client can use _anchor_ instead of _position_ to find the index of
an id within a large set of results.

The response to a call to _getFooList_ is called _fooList_. It has
the following arguments:

- ***accountId***: "String" The id of the account used for the call.

- ***filter***: "FilterCondition|null" The filter of the foo list.
  Echoed back from the call.

- ***sort***: "String[]|null" A list of Foo property names used to sort
  by. Echoed back from the call.

- ***state***: "String" A string encoding the current state on the
  server. This string MUST change if the results of the Foo list
  may have changed (for example, there has been a change to the
  state of the set of Foos; it does not guarantee that anything in
  the list has changed). It may be passed to _getFooListUpdates_ to
efficiently get the set of changes from the client’s current
state. Should a client receive back a response with a different
state string to a previous call, it MUST either throw away the
currently cached list and fetch it again (note, this does not
require fetching the foos again, just the list of ids) or, call
_getFooListUpdates_ to get the delta difference.

- ***canCalculateUpdates***: "Boolean" This is "true" if the server
  supports calling _getFooListUpdates_ with these "filter"/"sort"
  parameters. Note, this does not guarantee that the
  _getFooListUpdates_ call will succeed, as it may only be possible
  for a limited time afterwards due to server internal
  implementation details.

- ***position***: "Number" The 0-based index of the first result in the
  "ids" array within the complete list of results.
o *total*: "Number" The total number of foos in the foos list (given
the _filter_).

o *ids*: "String[]" The list of ids for each foo in the list after
filtering and sorting, starting at the index given by the
_position_ argument of this response, and continuing until it hits
the end of the list or reaches the "limit" number of ids. If
_position_ is >= _total_, this MUST be the empty list.

The following errors may be returned instead of the "fooList"
response:

"accountNotFound": An _accountId_ was explicitly included with the
request, but it does not correspond to a valid account.

"accountNotSupportedByMethod": The _accountId_ given corresponds to a
valid account, but the account does not support this data type.

"anchorNotFound": An anchor argument was supplied, but it cannot be
found in the message list.

"unsupportedSort": The _sort_ is syntactically valid, but includes a
property the server does not support sorting on.

"unsupportedFilter": The _filter_ is syntactically valid, but the
server cannot process it.

"invalidArguments": The request does not include one of the required
arguments, or one of the arguments is of the wrong type, or otherwise
invalid. A "description" property MAY be present on the response
object to help debug with an explanation of what the problem was.

4.5. getFooListUpdates

The "getFooListUpdates" call allows a client to efficiently update
the state of any cached foo list to match the new state on the
server. It takes the following arguments:

o *accountId*: "String|null" The id of the account to use for this
call. If "null", the primary account will be used.

o *filter*: "FilterCondition|null" The filter argument that was used
with _getFooList_.

o *sort*: "String[]|null" The sort argument that was used with
_getFooList_.

Jenkins                    Expires May 3, 2018                 [Page 30]
Internet-Draft                    JMAP                      October 2017

- **sinceState**: "String" The current state of the client. This is the string that was returned as the _state_ argument in the _fooList_ response. The server will return the changes made since this state.

- **maxChanges**: "Number|null" The maximum number of changes to return in the response. See error descriptions below for more details.

- **uptoId**: "String|null" The last id the client currently has cached from the list. When there are a large number of results, in a common case the client may have only downloaded and cached a small subset from the beginning of the list. If the sort and filter are both only on immutable properties, this allows the server to omit changes after this point in the list, which can significantly increase efficiency. If they are not immutable, this argument is ignored.

The response to _getFooListUpdates_ is called _fooListUpdates_. It has the following arguments:

- **accountId**: "String" The id of the account used for the call.

- **filter**: "FilterCondition|null" The filter of the foo list. Echoed back from the call.

- **sort**: "String[]|null" A list of Foo property names used to sort by. Echoed back from the call.

- **oldState**: "String" This is the "sinceState" argument echoed back; the state from which the server is returning changes.

- **newState**: "String" This is the state the client will be in after applying the set of changes to the old state.

- **uptoId**: "String|null" Echoed back from the call.

- **total**: "Number" The total number of foos in the current foo list (given the _filter_).

- **removed**: "String[]" The _id_ for every foo that was in the list in the old state and is not in the list in the new state. If the sort and filter are both only on immutable properties and an _uptoId_ is supplied and exists in the list, any ids that were removed but have a higher index than _uptoId_ SHOULD be omitted. If the server cannot calculate this exactly, the server MAY return extra foos in addition that may have been in the old list but are not in the new list. If the _filter_ or _sort_ includes a mutable
o *added*: "AddedItem[]" The id and index in the list (in the new state) for every foo that has been added to the list since the old state AND every foo in the current list that was included in the _removed_ array (due to a filter or sort based upon a mutable property). If the sort and filter are both only on immutable properties and an _uptoId_ is supplied and exists in the list, any ids that were added but have a higher index than _uptoId_ SHOULD be omitted. The array MUST be sorted in order of index, lowest index first. An *AddedItem* object has the following properties:

*  *id*: "String"
*  *index*: "Number"

The result of this should be that if the client has a cached sparse array of foo ids in the list in the old state:

```plaintext
fooIds = [ "id1", "id2", null, null, "id3", "id4", null, null, null ]
```

then if it *splices out* all foos in the removed array:

```plaintext
removed = [ "id2", ... ];
fooIds => [ "id1", null, null, "id3", "id4", null, null, null ]
```

and *splices in* (in order) all of the foos in the added array:

```plaintext
added = [{ fooId: "id5", index: 0, ... }];
fooIds => [ "id5", "id1", null, null, "id3", "id4", null, null, null ]
```

and *truncates* or *extends* to the new total length, then the foo list will now be in the new state.

The following errors may be returned instead of the "fooListUpdates" response:

"accountNotFound": An _accountId_ was explicitly included with the request, but it does not correspond to a valid account.

"accountNotSupportedByMethod": The _accountId_ given corresponds to a valid account, but the account does not support this data type.

"invalidArguments": The request does not include one of the required arguments, or one of the arguments is of the wrong type, or otherwise invalid. A _description_ property MAY be present on the response object to help debug with an explanation of what the problem was.
"tooManyChanges": There are more changes than the client’s `_maxChanges_` argument. Each item in the removed or added array is considered as one change. The client may retry with a higher max changes or invalidate its cache of the foo list.

"cannotCalculateChanges": The server cannot calculate the changes from the state string given by the client. Usually due to the client’s state being too old. The client MUST invalidate its cache of the foo list.

5. Binary data

Binary data is referenced by a `_blobId_` in JMAP, and uploaded/downloaded separately to the core API. A `_blobId_` does not have a name inherent to it, but this is normally given in the same object that contains the `_blobId_`. The data represented by a `_blobId_` is immutable.

Any `_blobId_` that exists within an account may be used when creating/updating another object in that account. For example, an Email type may have a `_blobId_` that represents the RFC5322 representation of the message. A client could create a new Email object with an attachment and use this `_blobId_`, in effect attaching the old message to the new one. Similarly it could attach any existing existing attachment of an old message without having to download and upload it again.

When the client uses a `_blobId_` in a create/update, the server MAY assign a new `_blobId_` to refer to the same binary data from the new/updated object. If it does so, it MUST return any properties that contain a changed `_blobId_` in the created/updated response so the client gets the new ids.

A `_blobId_` that is not referenced by a JMAP object (e.g. as a message attachment), MAY be deleted by the server to free up resources. Uploads (see below) are initially unreferenced blobs. To ensure interoperability:

- The server SHOULD use a separate quota for unreferenced blobs to the user’s usual quota.
- This quota SHOULD be at least the maximum total size that a single object can reference on this server. For example, if supporting JMAP Mail, this should be at least the maximum total attachments size for a message.
- When an upload would take the user over quota, the server MUST delete unreferenced blobs in date order, oldest first, until there is room for the new blob.
5.1. Uploading binary data

There is a single endpoint which handles all file uploads, regardless of what they are to be used for. To upload a file, the client submits an authenticated POST request to the file upload resource, the location of which can be found on the JMAP session object. The Content-Type MUST be correctly set for the type of the file being uploaded. The request MAY include an "X-JMAP-AccountId" header, with the value being the account to use for the request. Otherwise, the default account will be used.

A successful request MUST return a single JSON object with the following properties as the response:

- "accountId": "String" The id of the account used for the call.
- "blobId": "String", The id representing the binary data uploaded. The data for this id is immutable. The id only refers to the binary data, not any metadata.
- "type": "String" The media type of the file, as specified in [RFC6838], section 4.2.
- "size": "Number" The size of the file in bytes.

If identical binary content to an existing blob in the account is uploaded, the existing blobId MAY be returned.

5.2. Downloading binary data

The JMAP session object has a _downloadUrl_ property, which is in [RFC6570] URI Template (level 1) format. The URL MUST contain a variable called "blobId", MAY contain a variable called "accountId", and SHOULD contain a variable called "name".

The client may use this template in combination with an _accountId_ (if required in the URL template) and _blobId_ to download any binary data (files) referenced by other objects. Since a blob is not associated with a particular name, the template SHOULD allow a name...
to be substituted in as well; the server will return this as the filename if it sets a "Content-Disposition" header.

To download the data the client makes an authenticated GET request to the download URL with the appropriate variables substituted in. The client SHOULD send an "Accept" header with the content type they would like the server to return for the file. The "Content-Type" header of a successful response SHOULD be set to the type as requested in the "Accept" header by the client, or "application/octet-stream" if unknown and no "Accept" header given.

6. Push

Push notifications allow clients to efficiently update (almost) instantly to stay in sync with data changes on the server. In JMAP, push notifications occur out-of-band (i.e. not over the same connection as API exchanges), so that they can make use of efficient native push mechanisms on different platforms.

The general model for push is simple and sends minimal data over the push channel. The format allows multiple changes to be coalesced into a single push update, and the frequency of pushes to be rate limited by the server. It doesn’t matter if some push events are dropped before they reach the client; it will still get all changes next time it syncs.

6.1. The StateChange object

When something changes on the server, the server pushes a *StateChange* object to the client. A *StateChange* object has the following properties:

- *changed*: "String[TypeState]" A map of _account id_ to an object encoding the state of data types that have changed for that account since the last push event, for each of the accounts to which the user has access and for which something has changed. A *TypeState* object is a map. The keys are the plural type name "Foos" (e.g. "Mailboxes" or "Messages"), and the value is the _state_ property that would currently be returned by a call to _getFoos_. The client can compare the new state strings with its current values to see whether it has the current data for these types. If not, the changes can then be efficiently fetched in a single standard API request (using the _getFooUpdates_ type methods).

- *trigger*: "String" What caused this change. The following causes are defined:
* "delivery": The arrival of a new message caused the change.

* "user": An action by the user caused the change.

* "unknown": The cause of the change is unknown.

Future specifications may define further values. Clients MUST treat an unrecognised value the same as "unknown". Clients in battery constrained environments may use this information to decide whether to immediately fetch the changes.

6.2. PushSubscription

A push subscription is a message delivery context established between the client and a push service. A *PushSubscription* object has the following properties:

- *url*: "String" An absolute URL where the JMAP server will POST the data for the push message. This MUST begin with "https://".

- *expires*: "Date|null" The time this push subscription expires. If specified, the JMAP server MUST NOT make further requests to this resource after this time. It MAY automatically remove the push subscription at or after this time.

- *keys*: "Object|null" Client-generated encryption keys. If supplied the server MUST use them as specified in <https://tools.ietf.org/html/draft-ietf-webpush-encryption-09> to encrypt all data sent to the push subscription. The object MUST have the following properties:

  * *p256dh*: the P-256 ECDH Diffie-Hellman public key as described in <https://tools.ietf.org/html/draft-ietf-webpush-encryption-09>, encoded in URL-safe base64 representation as defined in [RFC4648].

  * *auth*: the authentication secret as described in <https://tools.ietf.org/html/draft-ietf-webpush-encryption-09>, encoded in URL-safe base64 representation as defined in [RFC4648].

Clients may register the push subscription with the JMAP server, which will then make a POST request to the associated push endpoint whenever an event occurs.

The POST request MUST have a content type of "application/json" and contain the utf-8 JSON encoded _StateChange_ object as the body. The
request MUST have a "TTL" header, and MAY have "Urgency" and/or "Topic" headers, as specified in section 5 of [RFC8030].

If the response code is "503" (Service Unavailable), the JMAP server MAY try again later, but may also just drop the event. If the response code is "429" (Too Many Requests) the JMAP server SHOULD attempt to reduce the frequency of pushes to that URL. Any other "4xx" or "5xx" response code MUST be considered a *permanent failure* and the push subscription should be deregistered (not tried again even for future events unless explicitly re-registered by the client).

The use of this push endpoint conforms with the use of a push endpoint by an Application Server as defined in [RFC8030]. A client MAY use the rest of [RFC8030] in combination with its own Push Server to form a complete end-to-end solution, or MAY rely on alternative mechanisms to ensure the delivery of the pushed data after it leaves the JMAP server.

6.2.1. setPushSubscription

Each session may only have a single push subscription registered. The push subscription is tied to the access token used to create it. Should the access token expire or be revoked, the push subscription MUST be removed by the JMAP server. The client MUST re-register the push subscription after re-authenticating to resume callbacks.

To set the push subscription, make a call to _setPushSubscription_. It takes the following argument:

- "pushSubscription": "PushSubscription|null" The PushSubscription object representing the endpoint the JMAP server will POST events to. This will replace any previously set subscription. Set to "null" to remove any previously registered subscription.

The response to _setPushSubscription_ is called _pushSubscriptionSet_. It has no arguments.

The following errors may be returned instead of the _pushSubscriptionSet_ response:

- "invalidUrl": Returned if the URL does not begin with "https://", or is otherwise syntactically invalid or does not resolve.

- "forbidden": Returned if the URL is valid, but for policy reasons the server is not willing to connect to it.
6.2.2.  getPushSubscription

To check the currently set push subscription (if any), make a call to `_getPushSubscription_`. It does not take any arguments. The response is called `_pushSubscription_` and it has a single argument:

- *pushSubscription*: "PushSubscription|null" The PushSubscription object the JMAP server is currently posting push events to, or "null" if none.

6.3.  Event Source

Clients that can hold open TCP connections can connect directly to the JMAP server to receive push notifications via a "text/event-stream" resource, as described in <http://www.w3.org/TR/eventsource/>. This is a long running HTTP request down which the server can push data.

When a change occurs in the data on the server, it pushes an event called *state* to any connected clients, with the _StateChange_ object as the data.

The server SHOULD also send a new event id that encodes the entire server state visible to the user immediately after sending a _state_ event. When a new connection is made to the event-source endpoint, a client following the server-sent events specification [1] will send a Last-Event-ID HTTP header with the last id it saw, which the server can use to work out whether the client has missed some changes. If so, it SHOULD send these changes immediately on connection.

The client MAY add a query parameter called "closeafter" with value "state" to the event-source resource URL when requesting the event-source resource. If set, the server MUST end the HTTP response after pushing a _state_ event. This can be used by clients in environments where buffering proxies prevent the pushed data from arriving immediately, or indeed at all, when operating in the usual mode.

The client MAY add a query parameter called "ping", with a positive integer value representing a length of time in seconds, e.g. "ping=300". The server MAY modify the value given to be subject to a minimum and/or maximum value. For interoperability, servers MUST NOT have a minimum allowed value higher than 30 or a maximum allowed value less than 300.

If set, the server MUST send an event called *ping* whenever this time elapses since the previous event was sent. This MUST NOT set a new event id. The data for the event MUST be a JSON object containing an _interval_ property, the value (type "Number") being
the interval in seconds the server is using to send pings (this may
be different to the requested value if the server clamped it to be
within a min/max value).

Clients can monitor for the _ping_ event to help determine when the
closeafter mode may be required.

Refer to the Authentication section of this spec for details on how
to get the URL for the event-source resource. Requests to the
resource must be authenticated.

A client MAY hold open multiple connections to the event-source
resource, although it SHOULD try to use a single connection for
efficiency.

7. Security considerations

7.1. Transport confidentiality

All HTTP requests MUST use [RFC5246] TLS (https) transport to ensure
the confidentiality of data sent and received via JMAP. Clients MUST
validate TLS certificate chains to protect against man-in-the-middle
attacks.

7.2. Authentication scheme

A number of HTTP authentication schemes have been standardised
(<https://www.iana.org/assignments/http-authschemes/http-
authschemes.xhtml>). Servers should take care to assess the security
characteristics of different schemes in relation to their needs when
deciding what to implement.

If offering the Basic authentication scheme a service MAY not allow a
user’s regular password but require generation of a unique app
password via some external mechanism for each client they wish to
connect.

7.3. Service autodiscovery

Unless secured by something like DNSSEC, autodiscovery of server
details is vulnerable to a DNS poisoning attack leading to the client
talking to an attacker’s server instead of the real JMAP server. The
attacker may then man-in-the-middle requests and depending on the
authentication scheme, steal credentials to generate its own
requests.
7.4. JSON parsing

The security considerations of [RFC7159] apply to the use of JSON as the data interchange format.

7.5. Denial of service

A small request may result in a very large response, and require considerable work on the server if resource limits are not enforced. JMAP provides mechanisms for advertising and enforcing a wide variety of limits for mitigating this threat, including limits on number of objects fetched in a single method call, number of methods in a single request, number of concurrent requests, etc.

JMAP servers MUST implement sensible limits to mitigate against resource exhaustion attacks.

7.6. Push encryption

When data changes, a small object is pushed with the new state strings for the types that have changed. While the data here is minimal, a passive man-in-the-middle attacker may be able to gain useful information. To ensure confidentiality, if the push is sent via a third party outside of the control of the client and JMAP server the client MUST specify encryption keys when establishing the PushSubscription.

The privacy and security considerations of [RFC8030] and <https://tools.ietf.org/html/draft-ietf-webpush-encryption-09> also all apply to the use of the PushSubscription mechanism.
